Abstract

The distribution functions of the codon usage probabilities, computed over all the available GenBank data, for 40 eukaryotic biological species and 5 chloroplasts, do not follow a Zipf law, but are best fitted by the sum of a constant, an exponential and a linear function in the rank of usage. For mitochondria the analysis is not conclusive. A quantum-mechanics-inspired model is proposed to describe the observed behaviour. These functions are characterized by parameters that strongly depend on the total *GC* content of the *coding regions* of biological species. It is predicted that the codon usage is the same in all exonic genes with the same *GC* content. The Shannon entropy for codons, also strongly depending on the exonic *GC* content, is computed.

1 Introduction

In the recent past, some interest has been shown in applying methods of statistical linguistics and information theory for the analysis of DNA sequences, in particular in investigating whether the frequency distribution of nucleotides or sequences of nucleotides follows Zipf's law [1], and using the Shannon entropy to identify the redundancy or the bias of a nucleotides sequence. Let us recall that, at the end of the forties, Zipf remarked that, in natural languages and in many other domains, the distribution function follows an inverse power law, which can be described, denoting by rank $n = 1$ the most used *word*, by $n = 2$ the next one and so on, and with $a > 0$, by

$$f_n = \frac{f_1}{n^a} . \quad (1)$$

In 1992, it was shown [2] that the distribution of the nucleotides in DNA follows a Zipf law of the type given by eq. (1). However, the opinions on this statement are divided, see [3]. Soon after [4, 5], it was shown that noncoding sequences of DNA are more similar to natural languages than the coding ones, and the Shannon entropy has been used to quantify the *redundancy* of word. This work also raised a debate in the literature [6]. Also, Zipf's law seems well adapted to represent the abundance of expressed genes, with an exponent $a \approx 1$, as can be seen in the recent work of ref. [7]. The origin of Zipf's law is thought to arise from stochastic processes [8], especially when they can be modelled as random walks in log scale [9]; for further analysis, see [10]. However, an analysis of the rank distribution for codons, performed in many genes for several biological species, led the authors of [12] to fit experimental data with an exponential function. In particular, by considering separately different coding DNA sequences, they studied the relation between the parameter in the exponential, the frequency of the rank one and the length of the sequence for different genes. From this very short overview, it follows that the determination of the kind of law the codon rank distribution follows is extremely interesting, in investigations of the nature of the evolutionary process, which has acted upon the codon distribution, i.e. the eventual presence of a bias.

In the last few years, the number of available data for coding sequences has considerably increased, but apparently no analysis using the whole set of data has been performed. The aim of this paper is to perform such a study. As the result of our investigation, we will point out that the rank of codon usage probabilities follows a universal law, the frequency function of the rank- n codon showing up as a sum of an exponential part and a linear part. A quantum-mechanics-inspired model is proposed, which provides for the form of the observed law and gives the correct sign in the different terms. Such a universal behaviour suggests the presence of general biases, one of which is identified with the total *exonic GC* content. Indeed, the values of the parameters appearing in the fitting expression are plotted versus the total percentage of exonic *GC* content of the biological species and are reasonably well fitted by a parabola. Finally, from the obtained expression, we derive the theoretical prediction that the usage probability for *rank-ordered* codons is the same in any genic region having the same exonic *GC* content for any biological species.

We compute the Shannon entropy [13] for amino-acids and find that its behaviour in function of the exonic *GC* content is also a parabola, whose apex is around the value 0.50 of the *GC* content.

2 Codon usage probabilities distribution

Let us define the usage probability for the codon XZN ($X, Z, N \in \{A, C, G, U\}$) as

$$P(XZN) = \lim_{n_{tot} \rightarrow \infty} \frac{n_{XZN}}{N_{tot}}, \quad (2)$$

where n_{XZN} is the number of times the codon XZN has been used in the analysed biosynthesis process for a given biological species and N_{tot} is the total number of codons used in all considered processes. It follows that our analysis and predictions hold for biological species with sufficiently large statistics of codons. For each biological species, codons are ordered following the decreasing order of the values of their usage probabilities, i.e. codon number 1 corresponds to the highest value, codon number 2 is the next highest, and so on. We denote by $f(n)$ the probability $P(XZN)$ of finding XZN is in the n -th position. Of course the same codon occupies in general two different positions in the rank distribution function for two different species. We plot $f(n)$ versus the rank and we determine that the best fit to the data can be reached by the sum of an exponential function, a linear function in the rank and a constant, i.e.

$$f(n) = \alpha e^{-\eta n} - \beta n + \gamma, \quad (3)$$

where $0.0187 \leq \alpha \leq 0.0570$, $0.050 \leq \eta \leq 0.136$, $0.82 \cdot 10^{-4} \leq \beta \leq 3.63 \cdot 10^{-4}$, $\gamma = 0,016$ are constant depending on the biological species. These four constants have to satisfy the normalization condition

$$\sum_n f(n) = 1. \quad (4)$$

In table 1 we list the 40 biological species (6 vertebrates, 4 plants, 3 invertebrates, 2 fungi and 25 bacteriae) – with a number of codons ranging between 800 000 and 20 000 000 in decreasing order (data from GenBank release 129.0 [17]), whose codon usage has been fitted, specifying for each biological species the value of the parameters, computed by a best-fit procedure and the corresponding χ^2 . Here and in the following, the χ^2 coefficient is defined by

$$\chi^2 = \sum_i \frac{(y_i - y(x_i))^2}{y(x_i)}, \quad (5)$$

where x_i are the experimental abscissae, y_i the experimental values and $y(x_i)$ the fitted ones. In some cases, $y(x_i)$ takes vanishing or negative values for a few points, hence the χ^2 is not reported. In figs. 1–4, we report the plot of $f(n)$ as a function of n for a few biological species (*Homo sapiens*, *Drosophila melanogaster*, *Arabidopsis thaliana*, and *Escherichia coli*). The plot has been cut to $n = 61$ to take into account the fact that in standard code there are three Stop codons (to end the biosynthesis process), whose function is very peculiar. For the same reason, the χ^2 has been computed by taking into account the 61 coding codons only. In table 6, we report the type of the twenty-first most used codons of the observed rank distribution $f(n)$. A similar study, for a sample of twenty vertebrates with a codon statistics larger than 100 000, reveals that, for almost all biological species, the four most used codons are *GAG*, *CUG*, *AAG* and *CAG*. All these codons have a *G* nucleotide in third position and three of them encode doublets. An analysis performed on the chloroplast codon usage for a sample of five plants gives the same result for the rank distribution $f(n)$, see table 2 and fig. 5 (*Chloroplast Arabidopsis thaliana*). We also report, in table 3, the values of the parameters and the χ^2 for a sample of nine mitochondriae with a codon statistics larger than

15 000. The fits for *Homo sapiens* and *Arabidopsis thaliana* are presented in figs. 6 and 7. We point out, however, that for mitochondriae the codon usage frequencies distribution for several species (e.g. *Arabidopsis thaliana* or *Drosophila melanogaster*) is ill fitted by eq. (3). It may be an indication that mitochondriae do not follow the universal law (3). Note that the mitochondrial codes have a few differences with the eukaryotic code and vary slightly between species, see e.g. [11]. In these cases, the χ^2 has been computed over the corresponding coding codons. The value of the constant γ is approximately equal to $1/61 = 0.0164$ or to $1/64 = 0.0156$, i.e. the value of the codon usage probability in the case of uniform and not biased codon distribution. Therefore the other two terms in eq. (3) can be viewed as the effect of the bias mechanism. The appearance of the linear term is more intriguing. Let us remark that in [12], where an exponential function is used to fit the rank of usage in genes (not the rank of usage probability), the linear term has not been observed, as its contribution becomes noticeable for approximately $n \geq 20$. Owing to the analysis of genes (with at most a few hundred codons), the fits in that paper end before this value of the rank. It is believed that the main causes of codon usage bias are the translational efficiency, the selection pressure and the spontaneous mutations. From the smallness of parameter β in (3), it is tempting to identify the latter as the consequence of mutation effect and the first term in (3) as the effect of selection pressure, i.e. the interaction with the environment.

Let us try to build up a simple model to explain the universal structure of eq. (3). In a physical quantum system, with discrete energy levels, the occupation number of the i -th energetic level is proportional to $\exp(-E_i/kT)$, where E_i is the energy of the level, T is identified with the temperature and k is the Boltzmann constant. Inspired by this analogy, let us assume that the rank of the probability distribution is a function of some kind of *energy*. In this case the codon usage probability is, for any codon, equal to $f(n) = \exp(-aE_n)$, where a is a positive constant. We assume that the system satisfies periodic conditions in the y and z directions, with a very small spacing in the z direction, so that the excited modes along this direction can be neglected, and that the interaction with the environment can be modelled as the switching on of a constant uniform *magnetic field* in the direction of the z axis. As a consequence, the Landau levels appear, the *energetic levels* now being in natural units

$$E_n - E_0 = \omega(n + 1/2) , \quad (6)$$

where ω is the so-called cyclotron frequency. The wave function is

$$\psi(x, y, z) = \Phi_n(x - lx_0) e^{ik_y y} e^{ik_z z} , \quad (7)$$

where

$$k_y = \frac{2\pi l}{L_y} , \quad k_z = \frac{2\pi}{L_z} , \quad l \in \mathbf{Z}, l \neq 0 , \quad (8)$$

and $\Phi_n(x - lx_0)$ is the wave function of the n -th energy level of a one-dimensional harmonic oscillator shifted by lx_0 ($x_0 = 2\pi/qBL_y$). There is a degeneracy due to the arbitrariness of k_y . A quantum charged physical system in an excited state spontaneously falls down to a lower state, the equilibrium configuration being the system in the fundamental state. In the case of codons, the equilibrium condition is the configuration where they occupy different “energy” levels, the situation being the analogue of a quantum system in the presence of an external pumping-back source. In order to model this situation in a simple way, we assume that the equilibrium probability distribution is a function $f(n) - f(n)_{B=0} = F(E_n, \gamma_n)$, where γ_n is the “spontaneous emission coefficient” of the n -th

level, which is taken to be very small because of the assumed equilibrium condition. We can make a first-order development in γ_n :

$$f(n) - f(n)_{B=0} = F(E_n, \gamma_n = 0) + \frac{dF}{d\gamma_n} , \quad (9)$$

where $dF/d\gamma_n$ is negative, the occupation probability decreasing with the increasing emission. We compute γ_n in the standard dipole approximation [14] between the n -th and the k -th levels ($k < n$). In the case of our model, we get

$$\gamma_n \propto n \delta_{k,n-1} . \quad (10)$$

So, replacing $F(E_n, \gamma_n = 0)$ by the Maxwell–Boltzmann expression, we obtain eq. (3). The values of the parameters depend on the biological species, as the selection pressure (in the model, the value of the *charge* and of the *magnetic field*) is different for different biological species. Even if our simple model is able to explain the universal behaviour and the right sign of the linear term, one should rather consider it as a toy model. However, the fact that one can build a simple mathematical scenario, able to reproduce the observed distribution, provides us with an indication of the existence of some strong physico-chemical constraints that add to the random effects.

Since it is well known that the *GC* content plays a strong role in the evolutionary process, we expect the parameters to depend on the total *GC* content of the genes region (here the total exonic *GC* content), which is indeed correlated with the evolution of the system (see [15] and references therein). We have investigated this dependence and report, in table 4, the fits of α and β to the total exonic *GC* content Y_{GC} of the biological species. One finds that the values of α and β are well fitted by polynomial functions (with $0 \leq Y_{GC} \leq 100$ in percentage):

$$\alpha = 0.21145 - 0.00776 Y_{GC} + 7.92 \cdot 10^{-5} Y_{GC}^2 , \quad \chi^2 = 0.0262 , \quad (11)$$

$$10^2 \beta = 0.10096 - 0.00345 Y_{GC} + 3.50 \cdot 10^{-5} Y_{GC}^2 , \quad \chi^2 = 0.0170 . \quad (12)$$

The two parameters α and β appear to be correlated. Indeed the plot representing β as a function of α is satisfactorily fitted by a regression line (see fig. 4):

$$10^2 \beta = 0.00851 + 0.375 \alpha , \quad \chi^2 = 0.0218 . \quad (13)$$

The value of the η parameter is largely uncorrelated with the total exonic *GC* content. Let us recall that, however, η is a function of α and β due to the normalization condition of eq. (4). Indeed we have (assuming $e^{-65\eta} \approx 0$)¹

$$1 = \frac{\alpha e^{-\eta}}{1 - e^{-\eta}} + 2080\beta + 64\gamma . \quad (14)$$

Using the fits for α and β , we can write the probability distribution function for any biological species, whose total *GC* content in per cent in the exonic regions is Y_{GC} , as

$$f(n) = (\alpha_0 + \alpha_1 Y_{GC} + \alpha_2 Y_{GC}^2) e^{-\eta n} - n(\beta_0 + \beta_1 Y_{GC} + \beta_2 Y_{GC}^2) + \gamma , \quad (15)$$

where η is obtained by solving eq. (14). Of course we are not able to predict which codon occupies the n -th rank. Finally, let us remark that the total exonic *GC* content Y_{GC} has to satisfy the consistency condition

$$Y_{GC} = \frac{1}{3} \sum_{i \in I} d_i f(i) , \quad (16)$$

where the sum is over the set I of integers to which the 56 codons containing *G* and/or *C* nucleotides belong and d_i is the multiplicity of these nucleotides inside the i -th codon.

¹Note that the result is almost unchanged if the data are normalized on the 61 coding codons.

3 Amino-acids rank distribution

It is natural to wonder if some kind of universality is also present in the rank distribution of amino-acids. From the available data for codon usage, we can immediately compute (using the eukaryotic code) the frequency of appearance of any amino-acid $F(n)$ ($1 \leq n \leq 20$) in the whole set of coding sequences. The calculated values as a function of the rank are satisfactorily fitted by a straight line,

$$F(n) = F_0 - Bn . \quad (17)$$

The parameters F_0 , B and the corresponding χ^2 for the fits are reported in table 7. A better fit can be obtained in general by using a third-degree polynomial; however, the range of the four parameters for this fit is larger than the range of the 2-parameter fit. For a few biological species, we give below the parameters for the two fits, see also the figures of table 9. The plots of the linear fits for few biological species are given in table 8. Note that the 21st point is just the contribution of the Stop codons, which of course has not been taken into account for the fits. One can remark that the most frequent amino-acid is always above the line. This can be easily understood in the light of eq. (3). Indeed, the most frequent amino-acids get, in general, a contribution of the exponential term of (3) with a low value of n .

Species	linear/cubic fits	χ^2
Homo sapiens	lin. $f = 0.087 - 0.0036n$	0.0072
	cub. $f = 0.099 - 0.0088n + 57 \cdot 10^{-5}n^2 - 1.7 \cdot 10^{-5}n^3$	0.0055
Arabidopsis thaliana	lin. $f = 0.088 - 0.0036n$	0.0068
	cub. $f = 0.099 - 0.0090n + 62 \cdot 10^{-5}n^2 - 1.95 \cdot 10^{-5}n^3$	0.0049
Drosophila melanogaster	lin. $f = 0.087 - 0.0036n$	0.0125
	cub. $f = 0.097 - 0.0096n + 76 \cdot 10^{-5}n^2 - 2.5 \cdot 10^{-5}n^3$	0.0042
Escherichia coli	lin. $f = 0.090 - 0.0039n$	0.0115
	cub. $f = 0.112 - 0.0136n + 105 \cdot 10^{-5}n^2 - 3.1 \cdot 10^{-5}n^3$	0.0067

Of course, the frequency of an amino-acid is given by the sum of the frequencies of its encoding codons given by (3). If the ranks of the encoding codons were completely random, we do not expect that their sum should take equally spaced values, as is the case in a regression line. Therefore, we can infer, for the biological species whose amino-acids frequency is very well fitted by a line, the existence of some functional constraints on the codon usage.

We report in table 10 the distribution of the amino-acids for the different biological species.

However, the behaviour predicted by eq. (3) fits the experimental data very well, while the shape of the distribution of amino-acids seems more sensible to the biological species. In fact, one can remark on many plots of the amino-acid distributions (see e.g. table 8), the existence of one or two plateaux, for which we do not have any explanation yet.

4 Consequences of probability distribution

We now derive a few consequences of eq. (3). In the following, we denote by y the *local* exonic *GC* content (i.e. for coding sequences of genes) for a given biological species. Let us assume that the exonic *GC* content of a biological species is essentially comprised in the interval $y_1 - y_0 = \Delta$ (e.g.

for *Homo sapiens* $y_0 = 35\%$ and $y_1 = 70\%$). We can write

$$f(n) = \frac{1}{\Delta} \int_{y_0}^{y_1} f(y, n) dy . \quad (18)$$

Since the l.h.s. of the above equation has the form given by eq. (3) for any n and for any biological species, if we do not want to invoke some “fine tuning” in the integrand function $f(y, n)$, we have to assume that

$$f(y, n) = a(y)e^{-\eta n} - b(y)n + \gamma \quad (19)$$

with the condition

$$\alpha = \frac{1}{\Delta} \int_{y_0}^{y_1} a(y) dy , \quad \beta = \frac{1}{\Delta} \int_{y_0}^{y_1} b(y) dy . \quad (20)$$

As a consequence, we predict that the codon usage probability is the same for any codon in any exonic genic region with the same GC content. The form of the $a(y)$ and $b(y)$ functions is yet undetermined. For *Homo sapiens*, we remark that the total exonic GC content Y_{GC} is, in a very good approximation, equal to the mean value of the interval $[y_0, y_1]$. Therefore, inserting (18) and (19) into (16), we derive that the functions $a(y)$ and $b(y)$ have to be *linear* functions of y . This theoretical derivation is in accordance with the conclusions of Zeeberg [16] obtained by an analysis for 7357 genes. On a quantitative level, using the numerical linear fits of Zeeberg, we find a very good agreement with our calculations. Note that this result is not in contradiction with eq. (15), since the previous analysis is valid for the fixed value of the exonic GC content for *Homo sapiens*. For bacteriae, the range of variation Δ of the local exonic GC content is very small. Therefore we expect the functions $a(y)$ and $b(y)$ to have the same shape as the functions α and β given in eqs. (11) and (12). Hence the functions α and β depend on the biological species.

We compute the Shannon entropy, given by

$$S = - \sum_n f(n) \log_2 f(n) \quad (21)$$

for the codons of a biological species and plot it versus the total exonic GC content; see figure in table 4. The Shannon entropy is rather well fitted by a parabola:

$$S = 2.2186 + 0.144 Y_{GC} - 0.00146 Y_{GC}^2 , \quad \chi^2 = 0.0315 . \quad (22)$$

Note that the parabola has its apex for $y \approx 0.50$, which is expected for the behaviour of the Shannon entropy for two variables (here GC and its complementary AU).

The same behaviour have been put in evidence by analogous computations made by Zeeberg [16] for *Homo sapiens*. So it seems that the entropy in the gene coding sequences and the total exonic region entropy in function of the exonic GC content show the same pattern.

In conclusion, the distribution of the experimental codon probabilities for a large total exonic region of several biological species has been very well fitted by the law of eq. (3). The spectrum of the distribution is universal, but the codon, which occupies a fixed level, depends on the biological species. Indeed, a more detailed analysis shows that, for close biological species, e.g. vertebrates, a fixed codon occupies almost the same position in $f(n)$, while for distant biological species the codons occupy very different positions in the rank distribution. We have also derived that the codon frequency for any genic region is, for fixed biological species and fixed GC content, the same. Entropy

analysis has shown that the behaviour observed in the genes with different GC content for the same biological species is very similar to the one shown by the total exonic region with different GC content for the different biological species.
